Background. Stored red blood cells (RBCs) accumulate biochemical and biophysical changes, known as storage lesion. The aim of this study was to re-challenge current data that anaemia in chronically anaemic haematology patients is not associated with low skeletal muscle tissue oxygen (StO₂), and that RBC storage age does not influence the tissue response after ischaemic provocation, using near-infrared spectroscopy.

Patients and methods. Twenty-four chronic anaemic haematology patients were included. Thenar skeletal muscle StO₂ was measured at rest (basal StO₂), with vascular occlusion testing (upslope StO₂, maximum StO₂) before and after transfusion.

Results. Basal StO₂ was low (53% ± 7%). Average RBC storage time was 10.5 ± 3.9 days. Effects of RBC transfusions were as follows: basal StO₂ and upslope StO₂ did not change significantly; maximum StO₂ increased compared to baseline (64 ± 14% vs. 59 ± 10%, p = 0.049). Change of basal StO₂, upslope StO₂ and maximum StO₂ was negatively related to age of RBCs. The decrease of maximum StO₂ was predicted (sensitivity 70%, specificity 100%), after receiving RBCs ≥ 10 days old.

Discussion. Resting skeletal muscle StO₂ in chronic anaemic patients is low. RBC storage time affects skeletal muscle StO₂ in the resting period and after ischaemic provocation.

Key words: skeletal muscle; tissue oxygenation; red blood cells; transfusion; storage lesion

Introduction

Anaemia is state of decreased blood oxygen carrying capacity.¹ Acute anaemia is associated with increased tissue oxygen extraction.² On the other hand, with chronic anaemia human body has time to at least partially adapt to decreased blood oxygen carrying capacity.³,⁴

Near-infrared spectroscopy (NIRS) is non-invasive method to assess tissue oxygenation (StO₂) and estimate tissue haemoglobin (THb) levels.⁵ We have studied skeletal muscle StO₂ in critically ill patients with preserved oxygen (i.e., cardiogenic shock) and with impaired oxygen extraction (i.e., septic shock).⁶-⁹ In addition to measuring resting StO₂ we performed vascular occlusion tests to stop arterial blood flow, to estimate oxygen consumption, and at the end of the occlusion, it was also possible to estimate vascular reactivity and maximal reperfusion capability.¹⁰

Under acute blood loss in trauma patients, the skeletal muscle StO₂ measured by NIRS correlates with blood haemoglobin (Hb) and delivery of oxygen, and can easily detect latent stage of haemorrhagic shock.¹¹ Unexpectedly, chronically anaemic haematology patients with preserved oxygen ex-
traction capability did not show low skeletal StO₂ and THb index despite their severe anaemia, which is what would be predicted from normal physiological responses.12

It is known that there are structural and functional changes to RBCs during storage. Recent study detected deleterious effects of RBC storage on microvascular responses to transfusion in stable anaemic trauma patients.13

The aim of the present study was to re-challenge the current data that anaemia in chronically anaemic haematology patients is not associated with low skeletal muscle StO₂, and that the age of RBCs does not influence tissue responses. We investigated these aspects using improved technology NIRS devices, for deeper tissue penetration and removal of the superficial signal from the skin.

**Materials and methods**

The study was approved by the National Medical Ethics Committee of the Republic of Slovenia (N°117/06/12, 29.06.2012). All of the patients were informed of the goals of the study, and signed their written consent. This study was carried out according to the Helsinki-Tokyo Declaration.

**Patients**

This prospective observational study included patients that were treated in the Outpatient Haematology Clinic of Clinical Department of Haematology, University Medical Centre Ljubljana. All of the patients included were in need of a blood transfusion, which was ordered by treating physicians who were not involved in the study. The exclusion criteria were age <18 years, and patient rejection of participation.

**Transfusions**

Leucodepleted RBC units in saline-adenine-glucose-mannitol additive solution and with maximal allowed haemolysis of 0.8% were acquired from the Blood Transfusion Centre of Slovenia. The patients were transfused with two units of RBCs with maximal age difference of 3 days.

**Near-infrared spectroscopy measurements and analysis**

The thenar skeletal muscle StO₂ and THb concentrations were measured with tissue spectrometer (Equanox 7600; Nonin Medical, Minnesota, USA). The electrode (8004CA, Equanox Advance Sensor, Nonin Medical) was placed on the thenar eminence to measure the maximum resting StO₂. During measurements, there were no additional treatment procedures in place, except for the RBC transfusion. All of the patients were positioned in a semi-recumbent position.

In this resting period before the transfusion and after StO₂ signal stabilisation, the basal StO₂ (%), and THb(g/l) were determined. Then vascular occlusion test was performed, as reported previously.6 In short, a sphygmomanometer cuff was placed over the brachium, and the pressure cuff inflation was taken to 60 mmHg over systolic blood pressure, to stop the blood flow in brachial artery. The StO₂ decreased during this arterial occlusion, which was measured as the downslope StO₂ (%/min). After reaching a StO₂ of 40% (the minimum StO₂), the vascular occlusion is released, and the StO₂ begins to rise again. The rate of this increase is determined from the curve as the upslope StO₂ (%/min), as a surrogate marker of the microcirculatory reactivity. After the release of the occlusion, the StO₂ increases to higher values compared to the basal StO₂ due to post-ischaemic vasodilatation (5, maximum StO₂). The StO₂ then slowly returns to the basal StO₂.
which allowed a 1-Hz sampling rate. The data acquired were further analysed off-line using the Microsoft Excel 2010 software (Microsoft, WA, USA).

All of the NIRS measurements were carried out without knowing the exact age of RBCs.

**Vital functions measurements**

Heart rate and systolic and diastolic blood pressures were measured (IntelliVueMP30, Philips Healthcare, Netherlands) before and after the transfusions, 5 min before NIRS measurements. Blood pressure was measured on the opposite hand to that used for NIRS measurements. Thenar skin temperature was measured immediately before NIRS measurements with a non-contact infrared clinical thermometer (Geratherm Medical AG Germany) (measuring range 34.0°C to 42.2°C, accuracy of ± 0.2°C).

**Laboratory measurements**

The Hb(g/L) and haematocrit before the transfusions were acquired according to routine laboratory tests (CoulterLH750 Haematology Analyser, Beckman Coulter Inc, USA).

**Statistics**

The normal distribution of the data was tested using D’Agostino-Pearson tests. The data are given as means ± standard deviation (SD), as medians and 95% confidence interval (95% CI), or as absolute values (percentages based on the whole group or subgroup). Effects of transfusion on different variables were tested with paired samples T-test. Regression analysis was performed using Analysis of variance to test the effects of age of RBCs. ROC analysis and interactive dot diagram were used to find the age of RBCs, which predicted divergent response. MedCalc 13.0 software (MedCalc Software, Belgium) was used. P < 0.05 was considered as statistically significant.

**Results**

**Before the RBC transfusions**

Twenty-seven patients were initially included in the study. Two patients were excluded from further analysis due to technical difficulties while recording the NIRS, one because of received 3 units of RBCs. In remaining 24 patients, 11 (46%) were female. The mean age of the patients was 65 ± 12 years. Myelodysplastic syndrome was the cause of anaemia in 16 (67%) patients, plasmacytoma in 4 (17%), leukaemia in 3 (12%), amyloidosis in 1 (4%). The demographic data, laboratory values, haemodynamic variables and skeletal muscle NIRS data of the patients before the RBC transfusions are presented in Table 1.

Data are means ± SD

In all patients received 2 units of RBCs. The average storage time of the RBCs was 10.5 ± 3.9 days.

**After the RBC transfusions**

Compared to baseline Hb (77.9 ± 12.4 g/L vs. 94.4 ± 17.4 g/L, p < 0.01) and haematocrit (0.23 ± 0.04% vs. 0.30 ± 0.03%, p < 0.01) increased after transfusion.

Systolic arterial pressure appeared not to be greatly affected by the RBC transfusions (122 ± 19 mm Hg vs. 124 ± 21 mm Hg, p = 0.5). Diastolic arterial pressure increased (68 ± 10 mm Hg vs. 77 ± 16 mm Hg, p = 0.013) and heart rate decreased after transfusion (78 ± 17 bpm vs. 73 ± 17 bpm, p = 0.01) after transfusion.
The thenar skin temperature remained unchanged, while THb increased after transfusion (1.13 ± 0.14 g/L vs. 1.22 ± 0.17 g/L, p = 0.006).

Basal StO$_2$ under resting conditions before the vascular occlusion did not differ significantly before and after RBC transfusion (53 ± 7% vs. 55 ± 7%, p = 0.10). As well there was no significant change of the downslope StO$_2$ (-9.4 ± 4.9%/min vs. -10.3 ± 8.4 min, p = 0.29), the minimum StO$_2$ (39 ± 5% vs. 40 ± 3%, p = 0.57) and the upslope StO$_2$ (78 ± 51%/min vs. 82 ± 59/min, p = 0.736). The maximum StO$_2$ values increased after RBCs transfusion compared to pre-transfusion measurements (64 ± 14% vs. 59 ± 10%, p = 0.049).

The age of RBCs transfused influenced the skeletal muscle StO$_2$ in resting conditions and during vascular occlusion testing. With increasing age the basal StO$_2$ increased less (basal StO$_2$ = 9.3124 - 0.7016 * age of RBCs in days; slope CI95%: -1.3467 to -0.0565, p = 0.0344) (Figure 2A). While receiving RBCs ≥ 10days old, the decrease of basal StO$_2$ was predicted with sensitivity 63.6% and specificity 61.5% (Figure 2B). Upslope StO$_2$ was also negatively related to the age of RBCs (upslope StO$_2$ = 64.3744 - 5.9782 * age of RBCs in days; slope CI95%: -11.5759 to -0.380, p = 0.0374); while receiving RBCs ≥ 10days old, the decrease of the upslope StO$_2$ was predicted with sensitivity 63.6% and specificity 61.5% (Figures 3A, 3B). The change of maximum StO$_2$ was negatively related to RBCs age (Maximum StO$_2$ = 20.8870 - 1.4950 * age of RBCs in days; slope CI95%: -2.7347 to -0.2553, p = 0.0203); while receiving RBCs ≥ 10days old, the decrease of the maximum StO$_2$ was predicted with sensitivity 70% and specificity 100%. There was no relationship between change of Hb, THb and downslope StO$_2$ with age of RBCs.

**Discussion**

Our findings confirm the low resting thenar skeletal muscle StO$_2$ in chronic anaemic haematology patients, and also the positive effects of RBCs on maximum StO$_2$ after vascular occlusion test- after reperfusion. Age of RBCs was negatively related to change of basal, upslope and maximum StO$_2$; age of RBCs ≥ 10days was found to predict divergent response of skeletal muscle StO$_2$ different responses of skeletal muscle StO$_2$.

In these patients, the resting StO$_2$ (53% ± 7%) was lower than that expected for normal healthy volunteers (83% ± 4%). Studies that have including patients with acute anaemia have also reported low skeletal muscle StO$_2$. On the other hand, surprisingly, Yurku et al. did not detect such expected low StO$_2$ of thenar eminence in anaemic haematology outpatients$^{12}$, although their RBC transfusions were successful in improving these variables. The explanation for these contradictory data probably lies with the NIRS probe they used (length 15 mm; penetration, ca.7 mm). Their kind of probe mainly detects changes in skin and subdermal tissue, which is, however, not the main issue in clinical use of NIRS.$^{14}$ The thenar skin and subdermal tissue are 3–4 mm thick, and these layers are even
thicker for oedematous patients. By using probes with deeper penetration or devices that can filter out superficial layers and bones, the organ/skeletal muscle StO2 can be better monitored, which is also more interesting for daily clinical practice (i.e., the device used in the present study). The importance of the probe and site has been shown previously.\textsuperscript{15,16} Superficial structures are more prone to changes in peripheral circulation and ambient temperature.\textsuperscript{17}

Our data that show here that skeletal muscle StO2 in the resting period is influenced by age of the RBCs is supported by Leal-Noval \textit{et al.}, who showed increases in cerebral oxygenation in patients with severe traumatic brain injury if the RBCs were stored for < 19 days. Their data suggested an inverse association between increments in brain oxygen tension and RBC storage time.\textsuperscript{18}

Kiraly \textit{et al.} using 25 mm NIRS showed probe, that transfusion of older RBCs (> 21 days) resulted in decreased skeletal muscle StO2 in critically injured trauma patients. They reported a moderate correlation between increasing age of blood and decrease of oxygenation.\textsuperscript{19}

Recent study also confirmed the deleterious effects of RBC storage on microvascular responses to transfusion in trauma patients.\textsuperscript{13} The transfusion of relatively older RBC units was associated with a decline in both StO2 and perfused capillary vascular density. They even predicted a mean decrease in StO2 during the duration of the transfusion that was related to the RBC age (-0.1064 × age of transfusion in days).

Other studies carried out in septic patients did not confirm the present data that the age of the blood has an impact on the tissue saturation measured in the resting period.\textsuperscript{20,21} Patients in sepsis/septic shock have imbalanced autoregulation of the blood flow in their peripheral tissues.\textsuperscript{10} Volume resuscitated anaemic septic patients already have relatively high resting skeletal muscle StO2. Roberson \textit{et al.} did not find any differences in StO2 of the brain and of the thenar muscle of healthy volunteers after transfusion of one unit of RBCs that was either 7 or 42 days old.\textsuperscript{22}

In the present study, the divergent responses of resting thenar skeletal muscle StO2 after receiving old blood could not be simply explained by an elevation of their blood Hb content only in the patients treated with fresh blood, which will lead to the increases in the oxygen delivery to the tissue, because there was no relationship between Hb or THb and age of RBCs. There is another explanation possible. In most tissues ratio of the arteriole to capillary to venous compartments is approximate-
It was shown that NO metabolism becomes disturbed in blood with storage duration > 14 days. It was recently demonstrated that compared with freshly prepared RBCs, the consumption rates of NO increase approximately 40-fold and NO-dependent vasodilatation is inhibited 2–4-fold in 42-day-old RBCs. Using competition kinetics analysis, it was also recently demonstrated that compared with freshly prepared RBCs, the consumption rates of NO increase approximately 40-fold and NO-dependent vasodilatation is inhibited 2–4-fold in 42-day-old RBCs. Using competition kinetics analysis, it was also recently demonstrated that compared with freshly prepared RBCs, the consumption rates of NO increase approximately 40-fold and NO-dependent vasodilatation is inhibited 2–4-fold in 42-day-old RBCs.

This decreased vascular reactivity (upslope and maximum StO2) found in patients treated with older blood can also be explained in terms of more disturbance of NO metabolism in older blood. NO has an important effect on vascular homeostasis, which is known as NO-based vasodilatation. Post-ischaemic hyperaemia, which develops with vascular occlusion, is one of the most important and reproducible indicators of microcirculatory responses.

Bennett-Guerrero et al. studied effects of storage on the deformability of RBCs, on RBC-dependent vasoregulation, and on the changes in S-nitrosohaemoglobin (SNO-Hb) concentrations. They observed significant drop in SNO-Hb concentrations in RBCs only 3h after blood donation, which might have been a reason for decreased vasodilatation after RBC transfusions. Reynolds et al. determined that there is possible regeneration of SNO-Hb in the received RBCs in vivo, which enables RBC-dependent vasodilatation and optimisation of blood perfusion through the peripheral tissues.

The present study poses some new questions. Further studies should focus on the effects of NO scavenging in RBCs that are stored for longer; also, whether aged RBCs can also be used as a therapeutic option, such as for septic patients, who have excessively induced NO synthesis.

**Conclusions**

The resting skeletal muscle StO2 in chronically anaemic haematology patients is low. The RBC storage time affects the skeletal muscle tissue oxygenation of these patients.
